#### Abstract

Geometry optimizations at the $\mathrm{HF} / 3-21 \mathrm{G}\left({ }^{*}\right)$ and $\mathrm{HF} / 6-31 \mathrm{G}^{*}$ levels of $a b$ initio theory have been carried out for various isomers of model disubstituted phosphoranes $\mathrm{PH}_{3} X Y\left(X, Y=\mathrm{OH}, \mathrm{CH}_{3}, \mathrm{NH}_{2}\right.$, and SH). Reasonable agreement was obtained between the optimized geometries and available crystal structure data for analogous compounds. The isomers were further characterized by frequency calculations. The MP2/6-31G*//6-31G* + ZPE energy data reveal that the interactions between the ligands are relatively small ( $0-4 \mathrm{kcal} \mathrm{mol}^{-1}$ ) for the most stable conformations of the isomers. Hence, for these conformations the apicophilicities (based upon monosubstituted phosphoranes) are approximately additive. The less stable $\mathrm{PH}_{3} \mathrm{XY}$ conformations are in general transition states or higher-order saddle points, and their interligand interactions are larger in magnitude (up to $10 \mathrm{kcal} \mathrm{mol}^{-1}$ ); the results with these conformations suggest that apicophilicities may not be as additive for some highly substituted phosphoranes. © 1993 by John Wiley \& Sons, Inc.

## INTRODUCTION

To help understand the structures and energies of pentacoordinated phosphorus compounds, we extended our theoretical calculations of monosubstituted phosphoranes ${ }^{1}$ to some disubstituted derivatives. The intermediates in the Wittig reaction and in substitution reactions of tetravalent phosphorus compounds are closely related to acyclic and cyclic pentacoordinated phosphoranes multiply substituted by RO, R, $\mathrm{NR}_{2}$, and RS groups. ${ }^{2}$ Many effects have been invoked to explain the relative stabilities of isomeric-substituted phosphoranes including ligand electronegativity, ${ }^{3} \pi$-effects, ${ }^{4}$ ring strain, and steric interactions. ${ }^{5}$ Interpretations are in general based upon a trigonal bipyramidal model in which the preference of a group for the apical rather than equatorial position is referred to as its "apicophilicity." In various systems that have been studied, quantitative estimates of apicophilicity vary over a wide range. ${ }^{6}$ Ab initio calculations provide an important means to study these various factors in more detail. In our first article, ${ }^{1}$ a series of phosphoranes with first- and second-row substituents were calculated with full geometry optimizations at the HF/ 6-31G* ab initio level for various structures. For a number of substituents, such as $\mathrm{OH}, \mathrm{SH}, \mathrm{CH}_{3}$, etc., apical and equatorial conformations of approximate trigonal bipyramids are minima on the potential energy surface and were used to define an intrinsic apicophilicity. For the highly electropositive substi-

[^0]tuents $\mathrm{Li}, \mathrm{Na}, \mathrm{BeH}$, and MgH , the apical structures are minima but the equatorial conformations are transition states; the global minima for these cases are square pyramids. Thus, apicophilicities cannot be rigorously defined for these substituents. Similarly, the strongly electronegative substituents $F$ and Cl are so highly ionic that only the apical phosphoranes are minima; these substituents also do not lend themselves to a definition of apicophilicity based upon monosubstituted phosphoranes.

Recently, Deiters et al. ${ }^{7}$ calculated a set of phosphoranes comprised of all combinations of the ligand atoms hydrogen, chlorine, and fluorine using partially optimized geometries. They found the apicophilicities of fluorine and chlorine to be dependent upon the other substituents. We have previously shown that several polyfluorophosphoranes have well-defined minima and established pseudorotation paths between them. ${ }^{8}$ In the present work, we have chosen the "normal" ligands, $\mathrm{OH}, \mathrm{CH}_{3}, \mathrm{NH}_{2}$, and SH , and performed computations on various isomers and conformers of acyclic phosphoranes disubstituted by combinations of these ligands. The results help delineate the effects of disubstitution in phosphoranes.

## METHODS

Single-determinant restricted Hartree-Fock calculations were performed with the Gaussian $82^{9}$ and Gaussian $86^{10}$ programs on VAX 11/780 and CONVEX C1 computers. Optimizations with Schlegel's gradient technique ${ }^{11}$ and Baker's eigenvector-following algorithm ${ }^{12}$ were carried out within the symmetry
groups specified; further constraints were imposed in some cases. The standard basis set $6-31 \mathrm{G}^{* 13}$ was used for the optimizations. The $3-21 \mathrm{G}\left({ }^{*}\right)^{14}$ was used for many of the structures, and as found in other systems ${ }^{15}$ this basis set gives geometries close to that of $6-31 \mathrm{G}^{*}$. Harmonic vibrational frequencies were obtained from analytic second derivatives at $6-31 \mathrm{G}^{*}$ and zero-point energies were scaled by $0.89{ }^{16}$ Møller-Plesset (MP2) perturbation theory ${ }^{17}$ was employed for the electron correlation corrections. The MP2(FC)/6-31G*//6-31G* + ZPE (abbreviated as MP2) level should be reasonably reliable for energy comparisons. In our previous study, ${ }^{1}$ this level gave relative energies close (in general $< \pm 1 \mathrm{kcal} \mathrm{mol}^{-1}$ ) to the MP4/6-31G*//6-31G* + ZPE results.

## RESULTS AND DISCUSSION

In addition to general interest in the structures of disubstituted phosphoranes, a major concern in this study was the additivity of apicophilicities-the extent of their dependence upon other substituents. In preliminary studies involving disubstituted model phosphoranes including at least one fluorine or chlorine ligand, $\mathrm{PH}_{3} X Y(X=\mathrm{F}, \mathrm{Cl} ; Y=\mathrm{F}, \mathrm{Cl}, \mathrm{CN}$, $\mathrm{OLi}, \mathrm{BH}_{2},{ }^{18}$ the effective apicophilicities of fluorine and chlorine were found to be influenced substantially by the other substituents. This is in accord with the results of Dieters et al., ${ }^{7}$ but our first article showed F and Cl to be ill-suited for such investigations. For this reason, we focus our attention here on the other common ligands, $\mathrm{OH}, \mathrm{CH}_{3}, \mathrm{NH}_{2}$, and SH . Apicophilicities of the monosubstituted phosphoranes are summarized in Table I. This table compares the apicophilicities at the highest-level MP4/6-31G*/ $/ 6-31 \mathrm{G}^{*}+$ ZPE in our first article with the MP2(FC)/ $6-31 \mathrm{G}^{*} / / 6-31 \mathrm{G}+$ ZPE (MP2) calculations corresponding to the highest levels in the present article. The table shows the agreement between the two levels. It also summarizes that OH and SH have small preferences for the apical position, $\mathrm{CH}_{3}$ has a slightly larger equatorial preference, and $\mathrm{NH}_{2}$ has a large preference for an equatorial orientation.
To study the effect of disubstitution on apicophilicity, only trigonal bipyramidal (TP) configurations were calcualted. The energies of the disubsti-
tuted phosphoranes are given at several theoretical levels in Table II. These results are used to derive the relative energies (REs). Because of the importance of cyclic phosphoranes in which the rings are apical-equatorial (a-e), the energies are also given relative to the most stable a-e structure and are summarized for the various levels in Table III. It has been well established that $\sim 90^{\circ}$ apical-equatorial ligandligand interactions are in general more significant than $\sim 120^{\circ}$ diequatorial ligand-ligand interactions. ${ }^{19}$ In several cases, however, the diequatorial isomers are the global minima.
These REs may be compared to the corresponding sums of the apicophilicities of the two substituents, e.g., at MP2. These apicophilicity summation energies (ASEs) also are summarized in Table III. The difference between the RE and relative ASE values is a measure of the mutual interaction or effect of the two substituents. The energies of the disubstituted phosphoranes may also be compared with monosubstituted analogs by means of the isodesmic equation, eq. (1).

$$
\begin{equation*}
\mathrm{PH}_{3} \mathrm{XY}+\mathrm{PH}_{5}=\mathrm{PH}_{4} X+\mathrm{PH}_{4} Y \tag{1}
\end{equation*}
$$

In evaluating this equation, the appropriate monosubstituted phosphorane $\mathrm{PH}_{4} X$ and $\mathrm{PH}_{4} Y$ conformers are chosen in which the substituents have the same conformations (apical or equatorial) as in $\mathrm{PH}_{3} \mathrm{XY}$. The data for $\mathrm{PH}_{4} X, \mathrm{PH}_{4} Y$, and $\mathrm{PH}_{5}$ come from our previous study. ${ }^{1}$ Equation (1) gives the bond summation energies (BSEs), which also are summarized in Table III. Note that most BSE values are negative, that is, the disubstituted phosphoranes are in general less stable than their monosubstituted analogs relative to hydrogen. The BSE values indicate the net mutual interactions among ligands in $\mathrm{PH}_{3} X Y$ based upon the monosubstituted phosphoranes, $\mathrm{PH}_{4} \mathrm{X}$ and $\mathrm{PH}_{4} \mathrm{Y}$. These interactions include all five ligands (i.e., the hydrogens as well), but the main effect presumably is that involving the two substituents ( $X$ and $Y$ ). The ASEs and BSEs are both based upon the monosubstituted phosphoranes and hence are interrelated. The BSE difference between two isomers is equal to the difference between REs and $\operatorname{ASEs}\left[\right.$ i.e., $\mathrm{BSE}_{1}-\mathrm{BSE}_{2}=\mathrm{RE}_{(1,2)}-\left(\mathrm{ASE}_{2}-\mathrm{ASE}_{1}\right)$ ].
The structures calculated are shown in Figures 15. The numbers chosen for the structures in these

figures are in the order of increasing energy. Lowercase letters designate the substituents: $o, n, c$, and s refer to $\mathrm{OH}, \mathrm{NH}_{2}, \mathrm{CH}_{3}$, and SH , respectively. For a-e structures, the letter for the apical substituent is given first. Diapical and diequatorial isomers are indicated by the appropriate subscript 1 or 3 after the number. For each set of substituents, the number in parentheses is the energy (in $\mathrm{kcal} \mathrm{mol}^{-1}$ ) relative to the most stable isomer at the highest level. For convenience, the number of imaginary frequencies is given by a subscript. Geometry data are summarized in Table IV. The parameters are defined in scheme 1; the positions of the substituents in Figures 1-5 correspond to this scheme.

Scheme 1. General structure of a-e and diapical disubstituted phosphoranes defining the structural parameters in Table IV.

## $\left.\mathbf{P H}_{\mathbf{3}} \mathbf{( O H}\right)\left(\mathbf{N H}_{\mathbf{2}}\right)$

Several acyclic $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{NH}_{2}\right)$ isomers were optimized at the 6-31G* level and several were compared at the $3-21 \mathrm{G}$ * $^{*}$ ) level (Fig. 1). The resulting geometries for the two basis sets are almost the same. For monosubstituted phosphoranes, the most stable structures are those with an apical OH group and an equatorial $\mathrm{NH}_{2}$ with a planar amino group perpendicular to the equatorial plane. The corresponding disubstituted derivative with a planar amino group is a stable structure, 2on, and is a local minimum with all frequencies real. A similar structure with a pyramidal amino group was found to be a transition state of higher energy (Table II). The global minimum at MP2, however, is $\mathbf{1}_{\mathrm{e}}$ on with OH and planar $\mathrm{NH}_{2}$ groups both equatorial but it is only $1.0 \mathrm{kcal} \mathrm{mol}^{-1}$ more stable than $20 n$. In $\mathbf{1}_{\mathrm{e}}$ on, the NH and OH bonds essentially eclipse the apical PH bonds. At the SCF level, this structure is slightly less stable than $20 n$ (by $0.15 \mathrm{kcal} \mathrm{mol}^{-1}$ ). Conformations with apical amino groups, 3no and 4no, are much higher in energy as expected given the strong equatorial preference for $\mathrm{NH}_{2}$. With pyramidal amino groups, these compounds are local minima; corresponding structures with constrained planar amino groups have

two imaginary frequencies (Table II). In 5 no, the $\mathbf{O H}$ group was constrained to lie in the equatorial plane. This structure has three imaginary frequencies and a high relative energy. The comparable monosubstituted phosphorane also is unfavorable. ${ }^{1}$

The optimized bond lengths in these $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{NH}_{2}\right)$ isomers are in reasonable agreement with available crystal structure data. For example, the equatorial $\mathrm{P}-\mathrm{N}$ bond lengths are $1.640 \AA$ and 6, ${ }^{20}$ as well as 1.698 and $1.681 \AA$ in $7 .{ }^{21}$ In 2 on, the optimized $\mathrm{P}-\mathrm{N}$ bond length is $1.656 \AA$. The apical $\mathrm{P}-\mathrm{O}$ bond length, $1.710 \AA$ in 6 and $1.697 \AA$ in 7 , may be compared with $1.702 \AA$ in 20 .

6
From simple electrostatic considerations, elec-tron-withdrawing substituents $X$ in disubstituted phosphoranes, $\mathrm{PH}_{3} \mathrm{XY}$, should result in shorter P Y bonds whereas electron-donating $X$ groups should lengthen the $\mathrm{P}-\mathrm{Y}$ bond. The calculated geometries agree with this generalization. In $\mathrm{PH}_{4} \mathrm{NH}_{2}$, the apical $\mathrm{P}-\mathrm{N}$ bond length is $1.757 \AA$ and the equatorial value is $1.675 \AA$ at $6-31 \mathrm{G}^{*}$. In $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{NH}_{2}\right)$, the length of
the $\mathrm{P}-\mathrm{N}$ bond is reduced in all of the isomers because of the presence of the OH group but the changes are small. These shortenings are $-0.006 \AA$ $\left(\mathbf{1}_{\mathrm{e}} \mathrm{on}\right),-0.019 \AA(2 \mathrm{on}),-0.007 \AA\left(\mathbf{3}_{\mathrm{a}} \mathrm{on}\right),-0.038$ $\AA(\mathbf{4 n o})$, and $-0.012 \AA(5 n o)$. The OH group in the equatorial position (4no) shortens the apical $\mathrm{P}-\mathrm{N}$ bond more than an OH group in the apical position (2on). The $\pi$ electron-donating $\mathrm{NH}_{2}$ group lengthens the $\mathrm{P}-\mathrm{O}$ bond in diapically substituted $\mathbf{3}_{\mathbf{a}} \mathbf{o n}$ by

$0.011 \AA$; but, in the apical-equatorial isomers the P O length hardly 'changes. For disubstituted phosphoranes, the $X P Y$ angle is the most significant. In $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{NH}_{2}\right)$, this angle is around $87-88^{\circ}$, close to that in an ideal trigonal bipyramid.

The BSE for the global minimum structure $\mathbf{1}_{\mathbf{e}}$ on has a relatively low magnitude. Because of the high preference for the amino group to be equatorial, its ASE relative to 2on is also small. For the other isomers, the ASE values are comparable to the relative energies and the BSE values are all comparable. All these results indicate that the mutual effects of the OH and $\mathrm{NH}_{2}$ substituents are relatively small.

tig reactions. ${ }^{22}$ The two pseudorotational forms of Wittig intermediates have similar energies. ${ }^{23}$

In monosubstituted phosporanes, the methyl group has a small preference for the equatorial position (apicophilicity, -0.9 ), slightly greater than the apical preference for the OH group (apicophilicity, $0.5)$. The global minimum found for the disubstituted compound has the OH apical and the methyl equatorial (loc). The five acyclic $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{CH}_{3}\right)$ isomers optimized in $C_{s}$ symmetry all have nearly ideal trigonal bipyramidal structures. The $\mathrm{OH}-\mathrm{CH}_{3}$ interactions in the three most stable isomers (Fig. 2) are

all small (less than $0.5 \mathrm{kcal} \mathrm{mol}^{-1}$ at MP2 for $\mathbf{l o c}$, 2oc, and 3co). These three isomers are all confirmed to be energy minima by frequency calculations. Again, the ASE relative energy predictions for these three isomers are accurate within $0.2 \mathrm{kcal} \mathrm{mol}^{-1}$.

The OH and one of the $\mathrm{CH}_{3}$ hydrogens in the $C_{s}$ plane of the 4oc and 5oc conformations point toward each other. Steric repulsion results in an increase in the OPC angles to $95.8^{\circ}$ in 40 c and to $92.5^{\circ}$ in 5oc. As expected, the ASEs for these two conformations deviate from the REs (Table III) due to these steric effects.

Attempts to find diequatorial isomers gave optimizations back to one of the above structures.

## $\mathbf{P H}_{3}\left(\mathbf{N H}_{2}\right)\left(\mathbf{C H}_{3}\right)$

For monosubstituted phosphoranes, both methyl and amino groups prefer the equatorial position. The
global minimum for the corresponding disubstituted compound, $\mathbf{1}_{\mathrm{e}} \mathbf{c n}$, in a $C_{s}$ structure with both substituents equatorial. The $\mathrm{NH}_{2}$ group is slightly pyramidal (sum of bond angles about nitrogen is $359.18^{\circ}$ ) away from methyl. Four a-e isomers of $\mathrm{PH}_{3}\left(\mathrm{NH}_{2}\right)\left(\mathrm{CH}_{3}\right)$ were calculated (Fig. 3). Both apical and equatorial $\mathrm{NH}_{2}$ groups were restrained to planarity. Isomer 2cn, the most stable of these structures, is a local minimum with all frequencies real, indicating that the $\mathrm{NH}_{2}$ group, as in the monosubstituted equatorial phosphorane, is indeed planar. The isomer 3cn differs only in the rotation of the methyl group and is the transition state for $\mathrm{P}-\mathrm{CH}_{3}$ rotation with a barrier of $3.5 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ at MP2. Isomers 4nc and 5nc each have one imaginary frequency, 545 i and $541 \mathrm{i} \mathrm{cm}^{-1}$, respectively, representing the transformation of planar $\mathrm{NH}_{2}$ to pyramidal $\mathrm{NH}_{2}$. They also have a second imaginary frequency of 215 i and $266 \mathrm{i} \mathrm{cm}^{-1}$, respectively, corresponding
to the pseudorotation of the $\mathrm{NH}_{2}$ group from apical to equatorial. Indeed, during the optimizations of 4nc and 5 nc with pyramidal $\mathrm{NH}_{2}$ groups the N-P-C angles increase to about $120^{\circ}$ and the structures transform into diequatorially substituted isomers. Because the interligand interactions are similar for $2 \mathrm{cn}, 4 \mathrm{nc}$, and 5nc, the relative energies can be derived from the apicophilicities with errors less than $1.1 \mathrm{kcal} \mathrm{mol}^{-1}$. For 3cn, the ASE and RE deviations are larger.

## $\mathbf{P H}_{3}(\mathbf{O H})(\mathbf{O H})$

The hydroxy group in $\mathrm{PH}_{4} \mathrm{OH}$ is slightly apicophilic but with two hydroxy groups two diequatorial isomers are the most stable, albeit by small amounts. The global minimum, $\mathbf{1}_{\mathbf{e}} \mathbf{0 0}$, is $0.9 \mathrm{kcal} \mathrm{mol}^{-1}$ more stable at MP2 than the lowest a-e isomer, 300. $\mathbf{1}_{\mathbf{e}} \mathbf{0 o}$ is the anti-rotomer; the syn-rotomer $\mathbf{2}_{\mathrm{e}} \mathbf{0 0}$ is higher by $0.5 \mathrm{kcal} \mathrm{mol}^{-1}$. Five acyclic isomers of dihydroxyphosphoranes were optimized at 6-31G* (Fig. 4). Two diapical isomers are only slightly less stable ( $<1$ kcal $\mathrm{mol}^{-1}$ ) than 300. Accordingly, the $\mathrm{P}-\mathrm{O}$ bond in the diapical dihydroxyphosphorane $\mathbf{4}_{\mathrm{a}} \mathbf{0 0}$ is only slightly shortened by $0.005 \AA$ compared to the value in monosubstituted apical $\mathrm{PH}_{4} \mathrm{OH}$. In $\mathbf{4}_{\mathbf{a}} \mathbf{0}$ o, the two OH groups bend toward each other; the OPO angle is $172.9^{\circ}$. The other diapical comformation $\mathbf{5 a}_{\mathbf{a}} \mathbf{0 o}$ has a slightly higher energy and is a transition state on the PES of $\mathrm{PH}_{3}(\mathrm{OH})(\mathrm{OH})$.

Three acyclic a-e dihydroxyphosphoranes were investigated in $C_{s}$ symmetry, 300, 600, and 700. The most stable of these forms is $\mathbf{3 0 0}$, with two OH groups bent in the same direction around the central phosphorus. This propeller-like conformation is also found in many crystal structures of multialkoxy-substituted phosphoranes such as 8 and $9 .{ }^{24}$

8

9

In 3oo, the distance between the oxygen in the apical hydroxy group and the hydrogen in the equatorial hydroxy group is $2.0 \AA$, close to the limit for $\mathrm{H}-\mathrm{O}$ hydrogen bonding. The electrostatic interactions certainly are favorable in this conformation. The BSE value for $\mathbf{3 0 o}$ is close to that of $\mathbf{4}_{\mathrm{a}} \mathbf{0 0}$; hence, ASE is similar to the calculated relative energy.

The ligand interactions in the other two a-e conformations are larger: -9.7 and $-10.0 \mathrm{kcal} \mathrm{mol}^{-1}$ for $\mathbf{6 0 0}$ and 700 , respectively. This effect is also reflected in the higher relative energies of $\mathbf{6 0 0}$ and 7oo. These higher energies can be attributed to the unfavorable electrostatic interactions between the two OH groups. Conformations of $\mathbf{6 0 0}$ and $\mathbf{7 0 0}$ (or distorted forms) exist commonly in TP spirobicyclic phosphorane compounds. ${ }^{2}$ The nonadditivity of
these conformations points to an additional source of strain in the cyclic phosphoranes. In particular, comparison of 600 with $\mathbf{3 0 0}$ confirms the effect noted in our first article ${ }^{1}$ : Cyclic dioxophosphoranes that resemble 600 contain an instability associated with the orientation of substituents about the oxygen in addition to any ring strain effects.

## $\mathbf{P H}_{3} \mathbf{( O H ) ( S H )}$

From variable-temperature nuclear magnetic resonance (NMR) studies, Trippett et al. has shown that oxy-, thic and selenogroups have comparable apicophilicities in pentacoordinated phosphoranes. For example, ethoxy- and ethylthio groups have similar preferences for an apical position, ${ }^{25}$ and phenoxy-, phenylthio-, and phenylseleno groups possess comparable apicophilicities. ${ }^{26}$ These results were also confirmed in our model $\mathrm{PH}_{4} \mathrm{XH}(X=\mathrm{O}, \mathrm{S})$ calculations, ${ }^{1}$ which gave OH and SH apicophilicities of 0.5 and $0.3 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. The disubstituted phosphoranes $\mathrm{PH}_{3}(\mathrm{OH})(\mathrm{SH})$ calculated here are analogous to the $\mathrm{PH}_{3}(\mathrm{OH})_{2}$ system. Although both OH and SH groups are modestly apicophilic, the global minimum, $\mathbf{1}_{\mathrm{e}} \mathbf{o s}$, for the disubstituted phosphorane is diequatorial but by only a small amount ( $0.4 \mathrm{kcal} \mathrm{mol}^{-1}$ ) compared to the diapical isomer, $\mathbf{2}_{\mathrm{a}} \mathbf{0}$. Both are more stable than the lowest a-e conformer. All five structures found are local energy minima and their geometries are close to the ideal trigonal bipyramid. The diapical isomer, $\mathbf{2}_{\mathbf{a}} \mathbf{0}$ s, and the lowest-energy a-e conformation, 3os, have BSEs similar to the corresponding $\mathrm{PH}_{3}(\mathrm{OH})\left(\mathrm{NH}_{2}\right)$ and $\mathrm{PH}_{3}(\mathrm{OH})_{2}$ structures. The higher-energy a-e conformations 40 and 5os have higher BSEs. The unfavorable electrostatic interactions in $40 s$ and 5 so raise the relative energies. Hence, deviations from apicophilicity additivity are significant for these less stable local minima.

## CONCLUSIONS

This work has demonstrated that the intrinsic ligand apicophilicities of $\mathrm{OH}, \mathrm{CH}_{3}, \mathrm{NH}_{2}$, and SH obtained from monosubstituted $\mathrm{PH}_{4} \mathrm{X}$ phosphorane models can be transferred to many of the disubstituted phosphorane combinations. This is especially true for the most stable conformations that are free from strong steric interactions. The summation of the apicophilicities of each ligand gives an estimate in general better than $2 \mathrm{kcal} \mathrm{mol}^{-1}$ for the relative energies of corresponding disubstituted isomers. This also provides a theoretical basis for the empirical experimental approach in which apicophilicities of ligands are deduced from multiply substituted phosphoranes. ${ }^{6 \mathrm{a}}$ Hence, the theoretically derived apicophilicities may also be applicable to mutisubstituted phosphoranes. Nevertheless, even these small en-
ergy differences can have significant conformational effects. For example, OH and SH groups that are apicophilic in monosubstituted phosphoranes prefer the diequatorial conformation in disubstituted phosphoranes although this preference is slight. Deviations of several kcal mol ${ }^{-1}$ do occur for less stable isomers. These high-energy structures are frequently not minima on the potential energy surface but they do also suggest that more highly substituted phosphoranes may show significant deviations from additivity.

Electronegative groups attached to the same central atom often interact strongly. This "generalized anomeric effect" involves $p$ interaction with an antibonding $\sigma^{*}$ orbital, optimum for an angle about $100^{\circ} .{ }^{27}$ The effects on tricoordinate phosphorus compounds have been analyzed in detail. ${ }^{27}$ Pentacoordinated phosphorus compounds can be expected to behave similarly provided suitable conformations are present. But, this is not generally the case for the stable isomers considered here. Thus, both $\mathbf{4}_{\mathbf{a}} \mathbf{0} \mathbf{o}$ and $\mathbf{2}_{\mathrm{a}} \mathbf{0 0}$ are diapical, for which $p \rightarrow \sigma^{*}$ anomeric interaction is negligible. Both loc and 2 en involve a methyl group, a relatively poor $\pi$ donor. In $\mathbf{3}_{\mathbf{a}} \mathbf{o n}$, the $N$ lone pair of the $\mathrm{NH}_{2}$ group is oriented $90^{\circ}$ with regard to the $\mathrm{P}-\mathrm{O}$ bond, precluding $\pi(p(N) \rightarrow$ $\left.\sigma^{*}(\mathrm{P}-\mathrm{O})\right)$ interaction. These are all examples in which RE and ASE differ by less than $1 \mathrm{kcal} \mathrm{mol}^{-1}$.

Finally, in all these examples the a-e conformations so important in cyclic phosphoranes are of relatively low energy and easily accessible even when not the lowest-energy structures.

This work was supported at Berkeley in part by NIH Grant GM30369 and by the UCSD Supercomputer Center and at Erlangen by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the CONVEX Computer Corporation. The Berkeley-Erlangen collaboration was also facilitated by NATO Grant $0772 / 86$. The authors thank Dr. Sjoerd Harder for technical assistance. This article was revised while one author (A.S.) was a guest of Professors Ugi and Hofacker at the Technical University, Munich, with support by the Alexander von Humboldt Stiftung, Bonn.

[^0]:    *Author to whom all correspondence should be addressed.

[^1]:    From ref. 1. Apicophilicities, $-\left(E_{\text {apical }}-E_{\text {equatorial }}\right)$, are in kcal mol ${ }^{-1}$.
    ${ }^{\text {a }}$ The apicophilicity of $\mathrm{NH}_{2}$ with a planar $\mathrm{NH}_{2}$ group at an apical position is $-8.6 \mathrm{kcal} \mathrm{mol}^{-1}$ at MP2/6-31G*// $6-31 G^{*}+$ ZPE; this value was used for the ASE calculations in Table III for those apical $\mathrm{NH}_{2}$ groups constrained to be planar.
